# Dynamic Atomic Congestion Games with Seasonal Flows 

Marc Schröder<br>Marco Scarsini, Tristan Tomala<br>Maastricht University<br>Department of Quantitative Economics

## Dynamic congestion games

- Most models of congestion games are static.
- The static game represents the steady state of a dynamic model with constant flow over time.
- Even if the flow of travellers is constant, how is the steady state reached?
- In real life traffic flows are rarely constant, although often (nearly) periodic. How does this affect the steady state?

## Edge dynamics

Each edge had a travel time and a capacity. For example, $\tau_{e}=2$ and $\gamma_{e}=2$.

## Edge dynamics

Each edge had a travel time and a capacity. For example, $\tau_{e}=2$ and $\gamma_{e}=2$.

## Edge dynamics

Each edge had a travel time and a capacity. For example, $\tau_{e}=2$ and $\gamma_{e}=2$.

## Edge dynamics

## Related literature

## Continuous time and flows

- Koch and Skutella (2011) provide a characterization of Nash flows over time via a sequence of thin flows with resetting.
- Cominetti, Correa and Larré (2011) prove existence and uniqueness of Nash flows over time.
- Macko, Larson and Steskal (2013) analyse Braess's paradox for flows over time.

## Discrete time and flows

- Werth, Holzhauser and Krumke (2014).

## Model

- A directed network $\mathscr{N}=\left(V, E,\left(\tau_{e}\right)_{e \in E},\left(\gamma_{e}\right)_{e \in E}\right)$ with a single source and sink, where
- $\tau_{e} \in \mathbb{N}$ is the travel time,
- $\gamma_{e} \in \mathbb{N}$ is the capacity.
- Time is discrete and players are atomic.
- Inflow is deterministic, but is allowed to be periodic.

## Model

- At each stage $t$, a generation $G_{t}$ of $\delta_{t}$ players departs from the source. Players are ordered by priority $\triangleleft$.
- At time $t$, player [it] observes the choices of players [js] $\langle[i t]$ and chooses an edge $e=(s, v) \in E$.
- Player [it] arrives at time $t+\tau_{e}$ at the exit of $e$.

## Model

- At this exit a queue might have formed by
(1) players who entered $e$ before $[i t]$,
(2) players who entered $e$ at the same time as [it], but have higher priority. Recall at most $\gamma_{e}$ players can exit $e$ simultaneously.
- When exiting edge $e=(s, v)$, player [it] chooses an outgoing edge $e^{\prime}=\left(v, v^{\prime}\right)$. This is repeated until player [it] arrives at the destination.

This defines a game with perfect information $\Gamma(\mathscr{N}, K, \delta)$.

## Latencies

- $c_{i t}(\sigma)=\sum_{e \in r_{i t}(\sigma)} \tau_{e}$ is the travel time of player [it],
- $w_{i t}(\sigma)$ is the waiting time of player [it],
- $\ell_{i t}(\sigma)$ is the total latency suffered by player [it]:

$$
\ell_{i t}(\sigma)=c_{i t}(\sigma)+w_{i t}(\sigma)
$$

- $\ell_{t}(\sigma)=\sum_{[i t] \in G_{t}} \ell_{i t}(\sigma)$ is the total cost of generation $G_{t}$.

## Solution concepts

- Equilibrium. Each player minimizes her own total latency given the queues in the system.
- Exists: multiple equilibria
- Subgame perfect Markov equilibrium
- Optimum. A social planner controls all players and seeks to minimize the long-run total costs, averaged over a period.

## Overview

## (1) Model

(2) Parallel networks

- Uniform departures
- Periodic departures
(3) Extensions
- Chain-of-parallel networks
- Braess's networks
- Series-parallel networks

4. Conclusion

## Uniform inflow

In a parallel network each route is made of a single edge. The capacity of the network is $\gamma=\sum_{e} \gamma_{e}$.

We assume that $\delta_{t}=\gamma$ for all $t \in \mathbb{N}$.

## Example

Inflow $=(3,3,3, \ldots)$. What happens in the equilibrium?

## Equilibrium

## Equilibrium

| $*$ | $*$ |  |
| $*$ | $*$ |  |
| $*$ | $*$ |  |
| $*$ | $*$ |  |
| $t=6$ |  |  |

## Equilibrium

## Equilibrium

## Optimum

## Can we do better in the long-run than 15 per generation?

## Optimum

## Can we do better in the long-run than 15 per generation?

## Optimum

## Can we do better in the long-run than 15 per generation?

## Optimum

Can we do better in the long-run than 15 per generation?

## Steady state

## Proposition

Let $\mathscr{N}$ be a parallel network. Then

$$
\begin{aligned}
\operatorname{WEq}(\mathscr{N}, \gamma) & =\gamma \cdot \max _{e \in E} \tau_{e} \\
\operatorname{Opt}(\mathscr{N}, \gamma) & =\sum_{e \in E} \gamma_{e} \cdot \tau_{e}
\end{aligned}
$$

## Steady state

## Proposition

Let $\mathscr{N}$ be a parallel network. Then

$$
\begin{aligned}
\operatorname{WEq}(\mathscr{N}, \gamma) & =\gamma \cdot \max _{e \in E} \tau_{e} \\
\operatorname{Opt}(\mathscr{N}, \gamma) & =\sum_{e \in E} \gamma_{e} \cdot \tau_{e}
\end{aligned}
$$

Equilibrium flows eventually coincide with optimal flows, but equilibrium costs are higher.

## Price of anarchy

- Let $\mathscr{N}$ be a parallel network. Then

$$
\operatorname{PoA}(\mathscr{N}, \gamma)=\frac{W E q(\mathscr{N}, \gamma)}{\operatorname{Opt}(\mathscr{N}, \gamma)} \leq \frac{\max _{e} \tau_{e}}{\min _{e} \tau_{e}}
$$

- The price of anarchy is unbounded over the class of parallel networks.

Example Bad network: $\tau_{1}=1, \gamma_{1}=N, \tau_{2}=N, \gamma_{2}=1$.

$$
\operatorname{PoA}(\mathscr{N}, \gamma)=\frac{(N+1) \cdot N}{2 N}
$$

## Periodic departures

- Inflow is a $K$-periodic vector:

$$
\delta=\left(\delta_{1}, \ldots, \delta_{K}\right) \in \mathbb{N}^{K}
$$

such that $\sum_{k=1}^{K} \delta_{k}=K \cdot \gamma$. We denote $\mathbb{N}_{K}(\gamma)$ the set of such sequences.

- When $\delta$ is not-uniform, queues have to be created when there is a surge of players.

## Example

Optimum for inflow (4,2,3).

## Example

Optimum for inflow (4,2,3).

Both in the equilibrium as in the optimum, the fourth player behaves as if he was postponed by one stage.

## Measure of periodicity

## Definition

For any two elements $\delta, \delta^{\prime} \in \mathbb{N}_{K}(\gamma)$, we say that $\delta^{\prime}$ is obtained from $\delta$ by an elementary operation if there exist an $i$ with $\delta_{i}>\gamma$ such that $\delta_{i}^{\prime}=\delta_{i}-1, \delta_{i+1}^{\prime}=\delta_{i}+1$.

Let $D(\delta)$ be the minimal number of elementary operations one has to perform to transform $\delta$ into $\gamma_{K}$.

## Measure of periodicity

Figure: 1 operation needed to transform $(3,1,2)$ into $(2,2,2)$.

## Measure of periodicity

Figure: 1 operation needed to transform $(3,1,2)$ into $(2,2,2)$.

Figure: 2 operations needed to transform (3, 2, 1) into (2, 2, 2).

## Steady state

## Theorem

Let $\mathscr{N}$ be a parallel network and $\delta \in \mathbb{N}_{K}(\gamma)$. Then

$$
\begin{aligned}
W E q(\mathscr{N}, K, \delta) & =K \cdot \gamma \cdot \max _{e \in E} \tau_{e}+D(\delta) \\
\operatorname{Opt}(\mathscr{N}, K, \delta) & =K \cdot \sum_{e \in E} \gamma_{e} \cdot \tau_{e}+D(\delta)
\end{aligned}
$$

## Steady state

## Theorem

Let $\mathscr{N}$ be a parallel network and $\delta \in \mathbb{N}_{K}(\gamma)$. Then

$$
\begin{aligned}
W E q(\mathscr{N}, K, \delta) & =K \cdot \gamma \cdot \max _{e \in E} \tau_{e}+D(\delta) \\
\operatorname{Opt}(\mathscr{N}, K, \delta) & =K \cdot \sum_{e \in E} \gamma_{e} \cdot \tau_{e}+D(\delta)
\end{aligned}
$$

Equilibrium flows eventually coincide with optimal flows.

- Series-parallel networks

## 4. Conclusion

## Parallel network below capacity

## Parallel network below capacity

## Equilibrium.

- If $\delta=3$, then $W E q(\mathscr{N}, 1, \delta)=9$.

## Parallel network below capacity

## Equilibrium.

- If $\delta=3$, then $W E q(\mathscr{N}, 1, \delta)=9$.
- If $\delta=(6,0)$, then $\operatorname{WEq}(\mathscr{N}, 2, \delta)=16<18$.

## Steady state below capacity

## Proposition

Let $\mathscr{N}$ be a parallel network with capacity $\gamma$ and let $\delta \in \mathbb{N}_{K}\left(\gamma^{\prime}\right)$, where $\gamma^{\prime} \leq \gamma$. Then

$$
W E q(\mathscr{N}, K, \delta) \leq K \cdot \gamma^{\prime} \cdot \max _{e \in E} \tau_{e}+D(\delta)
$$

## Chain-of-parallel network

## Chain-of-parallel network

Equilibrium. If $\delta=(6,0)$, then

## Chain-of-parallel network

Equilibrium. If $\delta=(6,0)$, then

## Chain-of-parallel network

Equilibrium. If $\delta=(6,0)$, then

| 3 | 4 | 5 | 6 |
| :---: | :---: | :---: | :---: |
| 1 | 2 |  |  |
| $*$ | $*$ | $*$ |  |
| $*$ | $*$ |  |  |

Equilibrium. If $\delta=(6,0)$, then

## Chain-of-parallel network

Equilibrium. If $\delta=(6,0)$, then

## Chain-of-parallel network

Equilibrium. If $\delta=(6,0)$, then

## Chain-of-parallel network

Equilibrium. If $\delta=(6,0)$, then

## Chain-of-parallel network

Equilibrium. If $\delta=(6,0)$, then

- $W E q(\mathscr{N}, 2, \delta)=22$ (earliest-arrival property).
- WEq* $(\mathscr{N}, 2, \delta)=25$ (no overtaking).
- $W E q^{* *}(\mathscr{N}, 2, \delta)=27$ (allow overtaking).

## Optimum

Let $F^{*}$ be the (static) min-cost flow. Define $M_{p}^{r}(\sigma)=\sum_{t=p K+1}^{(p+1) K} N_{p}^{r}(\sigma)$.

## Theorem

Let $\delta \in \mathbb{N}_{K}(\gamma)$. Then there exists an optimal strategy profile $\sigma$ such that $M_{p}^{r}(\sigma)=K \cdot F_{r}^{*}$ for each route $r$ and each period $p$, and

$$
\operatorname{Opt}(\mathscr{N}, K, \delta)=\operatorname{Opt}(\mathscr{N}, K, \gamma)+D(\delta)
$$

## Braess's network

## Braess's network

Worst equilibrium.

- Player [11] and [21] choose $e_{1} e_{3} e_{5}$.
- Player [12] chooses $e_{1} e_{3} e_{5}$ and [22] chooses $e_{2} e_{5}$.
- Player [13] chooses $e_{1} e_{3} e_{5}$ and [23] chooses $e_{1} e_{4}$.
- Player [14] chooses $e_{2} e_{5}$ and [24] chooses $e_{1} e_{3} e_{5}$.
- For $t \geq 5$, player [ $1 t$ ] chooses $e_{1} e_{4}$ and [2t] chooses $e_{2} e_{5}$.

Total costs $=3+3=6$.

## Braess's network

Best equilibrium.

- Player [11] chooses $e_{1} e_{3} e_{5}$ and [21] chooses $e_{2} e_{5}$.
- For $t \geq 2$, player [ $1 t$ ] chooses $e_{1} e_{4}$ and [2t] chooses $e_{2} e_{5}$. Total costs $=1+1=2$.

## Braess's network

## Proposition

For every even integer $n$, there exists a network $\mathscr{N}$ in which $|V|=n$ such that

$$
\operatorname{PoA}(\mathscr{N}, \gamma)=\frac{W E q(\mathscr{N}, \gamma)}{B E q(\mathscr{N}, \gamma)}=B R(\mathscr{N}, \gamma)=n-1
$$

## Series-parallel network

## Series-parallel network

## Equilibrium.

- Player [11] chooses $e_{2} e_{3}$, [21] chooses $e_{2} e_{4}$, [31] chooses $e_{2} e_{3}$.
- For $t \geq 2,[1 t]$ chooses $e_{1},[2 t]$ chooses $e_{2} e_{3},[3 t]$ chooses $e_{2} e_{4}$.

Total costs $=1+1+2=4$.

## Series-parallel network

- Suppose $e_{3}$ contains a queue, then total costs decrease to 3
- Another view on Braess's paradox: initial queues can improve total costs.

## Overview

## (1) Model

(2) Parallel networks

- Uniform departures
- Periodic departures
(3) Extensions
- Chain-of-parallel networks
- Braess's networks
- Series-parallel networks

4. Conclusion

## Summary

Two main contributions:

- We propose a measure of periodicity that characterizes the additional delay due to periodicity.
- We illustrate a new form of Braess's paradox: the presence of initial queues in a network may decrease the long-run costs in equilibrium.

## Open problems

- General networks
- Multiple sources and destinations
- Connection with continuous time and flows
- Stochastic inflow

## Apologies for congesting your brain.
