

# Treatment Recommendation and Parameter Estimation under Single-Index Contrast Function

**Menggang Yu**

Department of Biostatistics and Medical Informatics  
University of Wisconsin - Madison

Singapore, July 2017

# Background

- ▶ Increasing interest in discovering individualized treatment rules for patients who have different responses to treatments.
  - treatments may be no better than control overall, but may be better for a subgroup of patients with certain characteristics.
- ▶ Essentially, we need to investigate interactions between the treatments and covariates to identify the subgroup.

## Notations and Assumptions

For the  $i$ th patient,

- ▶  $T_i = 1$  or  $0$ : treatment indicator
- ▶  $Z_i = (1, Z_1, \dots, Z_p)$ :  $(p + 1)$ -vector of predictor variables, including an intercept
- ▶  $Y_i$ : observed outcome
- ▶  $\pi(Z_i) \equiv P(T_i = 1|Z_i)$ : treatment assignment mechanism
- ▶  $\pi(T_i|Z_i) = T_i P(T_i = 1|Z_i) + (1 - T_i) P(T_i = 0|Z_i)$

## Goal

- ▶ Construct a personalized scoring system  $f(Z)$
- ▶  $f(Z)$  ranks the patients according to the potential treatment effect (or **contrast function**)

$$\Delta(Z) = \mathbb{E}(Y | T = 1, Z) - \mathbb{E}(Y | T = 0, Z)$$

- ▶ Treatment is recommended for

$$\Omega = \{Z | f(Z) > 0\} \approx \{Z | \Delta(Z) > 0\}$$

## A Simple Interaction Model

- ▶  $\mathbb{E}(Y | Z, T) = \phi(Z) + T \times f(Z)$
- ▶  $\Delta(Z) = \mathbb{E}(Y | T = 1, Z) - \mathbb{E}(Y | T = 0, Z) = f(Z)$
- ▶ It is important to identify the treatment and covariate interactions.
- ▶ Main effects of covariates  $\phi(Z)$  is in some sense 'separated' from  $\Delta(Z)$ .

## Single Index Model for the Contrast Function

Consider the following single index model

$$\Delta(Z) = \mathbb{E}(Y|T = 1, Z) - \mathbb{E}(Y|T = 0, Z) = g(\beta^\top Z),$$

- ▶ Observe that

$$\mathbb{E}\left[\frac{(2T - 1)Y}{\pi(T|Z)} \mid Z\right] = \Delta(Z)$$

- ▶ Song et al (2007) considered estimation based on

$$\sum_i \left\{ \frac{(2T_i - 1)Y_i}{\pi(T_i|Z_i)} - g(Z_i\beta) \right\}^2$$

- ▶ Assuming  $\|\beta\| = 1$  and  $g$  from expansion of B-spline basis.

## Our Goal

- ▶ When  $g$  is monotone: even without estimating  $g$ ,  $\beta^\top Z$  is still interpretable in the sense of treatment assignment.
- ▶ If we assume  $g$  is monotone and the goal is treatment assignment, do we need to estimate  $g$ ? Will the results be better?
- ▶ Is there a systematic way to come up with estimation equations?
- ▶ Deal with high dimensional data
- ▶ Deal with multiple treatments

## Another Estimating Equation

Based on the work of Shuai et al (2017), define the risk

$$R_g(b) = \mathbb{E} \left[ \frac{\{Y - (T - 1/2)g(b^\top Z)\}^2}{\pi(T|Z)} \right].$$

- ▶  $R_g(b)$  is the expectation of

$$\begin{aligned} W_Z(b) = \mathbb{E} \left[ \left\{ Y - 2^{-1}g(b^\top Z) \right\}^2 \mid T = 1, Z \right] \\ + \mathbb{E} \left[ \left\{ Y + 2^{-1}g(b^\top Z) \right\}^2 \mid T = 0, Z \right] \end{aligned}$$

- ▶ The minimizer of  $R_g(b)$  is unique and equal to  $\beta$  if  $g$  is second order differentiable and  $g'$  is always positive.

## Another Estimating Equation

The empirical version of  $R_g(b)$  is

$$\frac{1}{n} \sum_{i=1}^n \frac{\{Y_i - (T_i - 1/2)g(b^\top Z_i)\}^2}{\pi(T_i|Z_i)}$$

If  $g$  were known, then we could estimate  $\beta$  by finding the solution of

$$\frac{1}{n} \sum_{i=1}^n \frac{\{Y_i - (T_i - 1/2)g(b^\top Z_i)\}}{\pi(T_i|Z_i)} (1 - 2T_i)g'(b^\top Z_i)Z_i = 0,$$

## Kernel Weighted Estimating Equation

Note that  $g'(0)(b^\top Z)$  is a good approximation to  $g(b^\top Z)$  near 0,

$$g(b^\top Z) \approx g(0) + g'(0)(b^\top Z) = g'(0)(b^\top Z).$$

We can estimate  $g'(0)\beta$ , via the following kernel based version,

$$\frac{1}{n} \sum_{i=1}^n \frac{\{Y_i - (T_i - 1/2)(b^\top Z_i)\}}{\pi(T_i|Z_i)} (1 - 2T_i)Z_i K_h(b^\top Z_i) = 0.$$

# Theoretical Results

- ▶ Assume that the kernel  $K$  satisfies the usual conditions;
- ▶  $h \rightarrow 0$  and  $nh \rightarrow \infty$  as  $n \rightarrow \infty$ ;
- ▶  $Z$  has a density  $f$ ;
- ▶  $\beta_j \neq 0$  for at least one  $j \geq 1$  and without loss of generality  $\beta_p \neq 0$ .

## Theoretical Results

Let  $\tilde{b}$  be a solution to the kernel weighted equation. Then, as  $n \rightarrow \infty$ ,

- (i)  $\tilde{b}$  converges in probability to  $g'(0)\beta$ .
- (ii) If  $nh^5 \rightarrow 0$ , then  $(nh)^{1/2}\{\tilde{b} - g'(0)\beta\}$  converges in distribution to the  $p$ -dimensional normal distribution with mean 0 and covariance matrix  $\Sigma$ .
- (iii) The optimal choice of  $h$  is  $h \asymp n^{-1/5}$ , where  $a \asymp b$  means  $a = O(b)$  and  $b = O(a)$ .

## Dealing with High Dimensional Covariates

When the dimension of  $Z$  is very high, we propose to add a LASSO penalty and solve

$$\frac{1}{n} \sum_{i=1}^n \frac{\{Y_i - (T_i - 1/2)(b^\top Z_i)\}}{\pi(T_i|Z_i)} (1 - 2T_i) Z_i K_h(b^\top Z_i) + \lambda s(b) = 0$$

where

- ▶  $\lambda \geq 0$  is a tuning parameter,
- ▶  $s(b)$  is the subgradient of  $p(b) = \sum_{j=1}^p |b_j|$  whose  $j$ th component is  $\text{sign}(b_j)$  if  $b_j \neq 0$  and  $c$  if  $b_j = 0$ ,  $0 < c < 1$ .

Let  $\hat{b}$  be a solution to the above equation. We can show that  $\hat{b}$  possesses a weak oracle property (Fan and Lv, 2011).

## Simulations

We consider respectively the low and high dimensional covariate settings under the following model,

$$Y = (\beta^\top Z/2)^2 + (T - 1/2)g(\beta^\top Z) + \epsilon,$$

where  $\epsilon \sim N(0, 0.3^2)$ ,  $\epsilon$ ,  $Z$  and  $T$  are independent, and  $g$  has the following three forms:

- ▶ linear model:  $g(\beta^\top Z) = 7\beta^\top Z$
- ▶ logistic model:  $g(\beta^\top Z) = 7 \{ \exp(\beta^\top Z) / \{1 + \exp(\beta^\top Z)\} - 1/2 \}$
- ▶ probit model:  $g(\beta^\top Z) = 7 \{ \Phi(\beta^\top Z) - 1/2 \}$ , where  $\Phi$  is the standard normal distribution

## Simulation - Low Dimensional Setting

- ▶ The treatment  $T$  takes 0 and 1 with equal probability.
- ▶  $p = 3$ ,  $\beta = (1, 1, 1, 1)^\top$ ,  $Z_1$ ,  $Z_2$ , and  $Z_3$  are independently distributed as the standard normal.
- ▶  $n = 200, 500$ , and  $1000$
- ▶ Bootstrap variance estimators with bootstrap size 1000.
- ▶ All methods produce negligible biases based on 1000 simulation runs.

## A Flexible Semiparametric Model

The single index contrast function model is equivalent to

$$Y = \frac{1}{2} T g(\beta^\top Z) + \epsilon,$$

- ▶  $g$  is an unknown function,
- ▶  $\epsilon$  satisfies

$$E \left[ \frac{T}{\pi(T|Z)} \epsilon(Z) \middle| Z \right] = 0.$$

This model is equivalent to the following model

$$Y = h(T, \beta^\top Z) + \epsilon(Z),$$

where  $\epsilon(Z)$  is some random variable satisfying the above equation.

# Semiparametric Efficiency Theory

The likelihood of  $(Z, T, Y)$  is

$$\eta_{10}(Z) \times \pi(T|Z) \times \eta_{20}\left\{Y - \frac{1}{2}Tg(\beta_0^\top Z), Z, T\right\}$$

- ▶  $\eta_{10}(\cdot)$  is the density of  $Z$
- ▶  $\eta_{20}(\cdot)$  is the density of  $\epsilon$  conditional on  $Z$  and  $T$
- ▶ Note that  $\eta_{10}$ ,  $\eta_{20}$ , and  $g$  are infinite-dimensional nuisance parameters.
- ▶  $\pi(T|Z)$  is either known or estimated by a parametric model

## Semiparametric Efficiency Theory

The orthogonal complement of the nuisance tangent space is

$$\mathcal{S}_0 = \mathcal{S}_{10} \oplus \mathcal{S}_2,$$

$$\mathcal{S}_{10} = \left\{ W_T \{ \alpha(Z) - \mathbb{E}[\alpha(Z) | \beta_0^\top Z] \} \left[ \epsilon - \frac{\mathbb{E}(W_T^2 \epsilon | Z)}{\mathbb{E}(W_T^2 | Z)} \right] : \forall \alpha(Z) \right\},$$

$$\mathcal{S}_2 = \left\{ W_T \gamma(Z) : \forall \gamma(Z) \right\}.$$

where

$$W_T \equiv \frac{T}{\pi(T|Z)}$$

## Semiparametric Efficiency Theory

For any function  $h(\epsilon, Z, T)$ , its projection on  $\mathcal{S}_0$  is given by

$$W_T C(Z) \left\{ \epsilon - \frac{\mathbb{E}[W_T^2 \epsilon | Z]}{\mathbb{E}[W_T^2 | Z]} \right\} + W_T \frac{\mathbb{E}[W_T h | Z]}{\mathbb{E}[W_T^2 | Z]},$$

where

$$C(Z) = W_{Z,T,\epsilon} \left\{ D(Z) - \frac{\mathbb{E}[W_{Z,T,\epsilon} D(Z) | \beta_0^\top Z]}{\mathbb{E}[W_{Z,T,\epsilon} | \beta_0^\top Z]} \right\},$$

$$W_{Z,T,\epsilon} = \left\{ \mathbb{E}[W_T^2 \epsilon^2 | Z] - \frac{\mathbb{E}[W_T^2 \epsilon | Z]^2}{\mathbb{E}[W_T^2 | Z]} \right\}^{-1},$$

$$D(Z) = \mathbb{E}[W_T h \epsilon | Z] - \frac{\mathbb{E}[W_T^2 \epsilon | Z] \mathbb{E}[W_T h | Z]}{\mathbb{E}[W_T^2 | Z]}.$$

## Efficient score

The efficient score is

$$W_T C(Z) \left\{ \epsilon - \frac{\mathbb{E}[W_T^2 \epsilon | Z]}{\mathbb{E}[W_T^2 | Z]} \right\},$$

where

$$C(Z) = W_{Z,T,\epsilon} g'(\beta_0^\top Z) \left\{ Z - \frac{\mathbb{E}[W_{Z,T,\epsilon} Z | \beta_0^\top Z]}{\mathbb{E}[W_{Z,T,\epsilon} | \beta_0^\top Z]} \right\},$$

and,

$$W_{Z,T,\epsilon} = \left\{ \mathbb{E}[W_T^2 \epsilon^2 | Z] - \frac{\mathbb{E}[W_T^2 \epsilon | Z]^2}{\mathbb{E}[W_T^2 | Z]} \right\}^{-1}.$$

# Efficiency Considerations

- ▶ In general, the efficient score is very hard to estimate directly
- ▶ Choose the most efficient estimating equation in a smaller subspace in the nuisance tangent space, e.g.,

$$\tilde{S} = \{W_T g'(\beta_0^\top Z) Z^\top \{\epsilon - \eta(Z)\}, \forall \eta(Z)\}.$$

- ▶ Choices for  $\eta(Z)$ 
  - ▶  $\eta(Z) = 0$ , adopted in our estimation.
  - ▶  $\eta(Z) = \{1 - 2\pi(Z)\}g(\beta_0^\top Z)$  for Song et al. (2017).
  - ▶  $\eta(Z) = \frac{E[W_T^2 \epsilon | Z]}{E[W_T^2 | Z]}$  leads to the most efficient estimator in  $\tilde{S}$  for any function  $g$ .

## Efficiency Considerations

When  $\eta(Z)$  does not need to be estimated, we propose minimizing the following loss function

$$\frac{\{Y - \frac{1}{2} Tg(\beta_0^\top Z) - \eta(Z)\}^2}{\pi(T|Z)}.$$

Formally, our MAVE-type estimator with  $\eta$ ,  $tMAVE_\eta$ , is defined to be the minimizer of the following optimization function:

$$\begin{aligned} & L(\beta, \{a_j, b_j\}_{j=1}^n) \\ &= \frac{1}{n^2} \sum_{j=1}^n \sum_{i=1}^n \frac{\{Y_i - \frac{1}{2} T_i[a_j + b_j(\beta^\top Z_i - \beta^\top Z_j) - \eta(Z_i)]\}^2}{\pi(T_i|Z_i)} w_{ij}, \end{aligned}$$

where  $w_{ij} = K_h(\beta^\top Z_j - \beta^\top Z_i)$ .

# Efficiency Considerations

A two step estimation process

- ▶ Firstly, we solve a tMAVE<sub>0</sub> (with  $\eta = 0$ ), then  $g$  and the residuals,  $\hat{\epsilon}_i$ 's, are estimated by kernel method.
- ▶ Then, we solve tMAVE<sub>eff</sub> by estimating  $\frac{E[W_T^2 \epsilon | Z]}{E[W_T^2 | Z]}$  by

$$\frac{\hat{E}[W_T^2 \hat{\epsilon} | Z]}{E[W_T^2 | Z]} = \pi(Z)(1 - \pi(Z)) \frac{\sum_{i=1}^n K_{h_e}^e(Z_i - Z) W_{T_i}^2 \hat{\epsilon}_i}{\sum_{i=1}^n K_{h_e}^e(Z_i - Z)} \quad (1)$$

where

- ▶  $K_{h_e}^e$  is a kernel function with  $K_{h_e}^e(Z) = h_e^{-p} K^e(Z/h_e^p)$ .
- ▶  $K^e$  can be different from the kernel used in tMAVE.

## Simulations

$$y = (\beta^\top Z)^2 + (T - 1/2)g(\beta^\top Z) + \epsilon,$$

- ▶ Almost the same as previous simulation setting;
- ▶ Main effect quadrupled;
- ▶ SD of the error term doubled:  $\sigma = 0.6$ .

## Conclusion and Discussion

- ▶ It is natural to extend the single index model to multiple index model

$$\Delta(Z) := \mathbb{E}[Y|T = 1, Z] - \mathbb{E}[Y|T = 0, Z] = g(B_0^\top Z),$$

where  $B_0$  is a  $p \times d$  matrix.

- ▶ Extension to multiple treatment is not trivial:
  - ▶ Choice of  $g$ :  $g_1, g_2, \dots$
  - ▶ Choice of  $\beta$  and model consistency: single vs. multiple index?
  - ▶ Treatment ordered?
